Abstract

INTRODUCTION

Peripheral nerve stimulators (Figure 1) have become indispensable as clinical and teaching tools in regional anesthesia practice. The advantage of using nerve stimulator over paresthesia technique include the ability to confirm the correct needle placement without inducing paresthesia. This, in turn, allows anesthesiologists to perform the block in sedated or anesthetized patients (1,2). Additionally, some have argued that avoiding paresthesias may reduce the risk of nerve damage, a frequently feared complication of neuronal blockade (3,4,5,6,7,8). Despite the common use of nerve stimulators, the common perception is that the techniques of peripheral nerve blockade (Figure 2) vary widely among anesthesiologists. Thus, in an attempt to assess the techniques of nerve stimulator-assisted peripheral nerve blockade we conducted a nation-wide survey on their use.
Figure 2
Figure 2. An example of peripheral nerve stimulator-guided peripheral nerve block. An insulated block needle attached to a nerve stimulator is advanced until the close proximity of the needle tip to the nerve is identified as contractions of the muscle groups innervated by the nerve being blocked. The current of the peripheral nerve stimulator is adjusted to the lowest current at which the contractions are still present (ideally <0.4mA).

METHODS
Questionnaires regarding the use of peripheral nerve blocks in their practices were mailed to 683 American anesthesiologists randomly selected from the ASA membership directory. Responses from attending anesthesiologists who reported performing peripheral nerve blockade in their practices were analyzed with respect to peripheral nerve stimulator utilization.

RESULTS
Among the 413 attending anesthesiologists who responded to the survey (an overall response rate of 60.5%), 268 (64.8%) reported that they use peripheral nerve stimulators when performing PNB. Although the majority (54.8%) (Figure 3) set their initial current between 0.3 mA and 1.0 mA, 34.7% use settings outside this range and 10.4% use the peripheral nerve stimulator without current display (Figure 4). More than half of the respondents (59.3%) achieve the optimal current on the peripheral nerve stimulator by selecting a high current initially and then decreasing the current according to the response elicited as the needle is advanced toward the nerve. Fewer anesthesiologists (32.7%) select a low current initially and then increase the current according to the elicited response (Figure 5). Nearly all anesthesiologists using peripheral nerve stimulator (81.5%) either always, or most of the time, seek the lowest current at which the appropriate response is still obtainable. Among those who perform more than 10 peripheral nerve blocks per month, 36% always seek the lowest stimulating current, and 47.4% do so most of the time. Anesthesiologists who perform more than 10 peripheral nerve blocks per month are more likely to manipulate the current output than anesthesiologists who less frequently perform peripheral nerve blocks (24.7% vs. 18%; p=0.008).

Discussion

The results of this survey indicate that the majority of American anesthesiologists use peripheral nerve stimulators in their regional anesthesia practice. However, there does not seem to be a uniform technique of using peripheral nerve stimulator during performance of peripheral nerve blockade. For instance, the choice of initial current settings widely vary among anesthesiologist as does the manner in which the optimal current is sought. Further studies designed to evaluate the efficiency of the various approaches are warranted as they may maximize the effectiveness of peripheral nerve stimulator in performing peripheral nerve blockade. Since anesthesiologists continuously manipulate the current from the initial setting to the low current before injection of local anesthetics, a search for a nerve stimulator with a better current control and more user-friendly control of the current is clearly indicated in order to facilitate performance of nerve blockade (9,10). (Figure 6).
