Abstract
Chylothorax is a rare cause of pleural effusion seen in approximately 2% of pleural effusions in adults and is associated with a 10% morbidity and mortality rate. Non-traumatic chylothorax in the adult is highly suggestive of malignancy, mainly lymphoma and metastatic carcinoma. Others etiologies include collagen vascular diseases and liver cirrhosis. Aggressive and early evaluation of pleural effusions is of the utmost importance, establishing the cause is essential in non-traumatic chylothorax. Pleural fluid and Radiologic studies including CT of the mediastinum and abdomen are recommended. We present a cases series and a review of non-traumatic chylothorax.

INTRODUCTION
Chylothorax is the occurrence of chylus in the pleural space and is characterized by pleural fluid (PF) with a turbid or milky white appearance due to high lipid content. The lipids in a chylothorax consist of triglycerides that enter the pleural space as chyle; most commonly from disruption of the thoracic duct. In a normal adult, the thoracic duct transports up to 4 L of chyle per day, allowing a rapid and large accumulation of fluid in the chest.

Chylothorax is a rare cause of pleural effusion seen in approximately 2% of pleural effusions in adults and is associated with a 10% morbidity and mortality rate. Chylothorax is usually classified as traumatic and non-traumatic; the prevalence after various cardiothoracic surgeries is 0.2-1%.

We report a series of three patients presenting with chylothorax and we discuss the literature.

CASE 1
A 46-year-old woman with no significant past medical history (PMH) was admitted to the Intensive Care Unit (ICU) with cough, dyspnea and fatigue of four days duration. She denied fever, weight loss or toxic habits. On examination she was tachypneic with a respiratory rate of 30/min, a pulse rate of 120/min, normal blood pressure and temperature. There were decreased breath sounds in both lungs fields and a one cm left supraclavicular lymph node nonmatted, nontender was noted. Initial laboratory showed a white blood cell count 6,000/mm3, hemoglobin 11 g/dl, liver and renal functions were normal. Chest roentgenogram (CXR) showed bilateral large pleural effusion and lower lobe alveolar infiltrates. Pleural fluid (PF) obtained from the left pleural space was consistent with an exudative neutrophilic effusion and normal triglycerides (TG). Patient was started on antibiotics for possible community acquired pneumonia. Results of respiratory, PF, blood cultures and HIV test were negative. The patient's condition continued to deteriorate and she underwent a CT guided right thoracentesis on the third day of admission. The PF was an exudative lymphocytic chylous effusion with TG of 490 mg/dL (Table 1). Cytology of the right PF showed atypical lymphocytes. Lymph node biopsy of the supraclavicular node revealed Non Hodgkin’s Lymphoma (diffuse B large cell). The patient was given chemotherapy and after a prolonged hospital stay she was discharged home with complete resolution of the pleural effusions.

CASE 2
A 39 y/o male with AIDS was admitted with severe dyspnea of one-week duration. Remarkable PMH was Kaposi Sarcoma (KS) of the oral cavity. The patient had not received any treatment for the KS. On examination he was tachypneic (respiratory rate of 25/min), there were purple lesions in the upper palate and lower extremities and decreased breath sound in both lungs. The CXR showed large bilateral effusion. Thoracentesis of the left side revealed an exudative serosanguineous lymphocytic effusion with TG of 255 (Table 1). The patient refused all medical intervention and he died shortly after admission.
CASE 3

A 42-year-old male with history of AIDS and liver cirrhosis due to Hepatitis C was admitted with fever, cough and respiratory failure that required intubation and mechanical ventilation. Examination revealed a cachectic man, febrile to 101°F, tachypneic with decreased breath sounds in the right side of the thorax and questionable ascitis on abdominal examination. A massive right pleural effusion was seen on CRX; thoracentesis showed a transudative effusion with TG of 184 mg/dL (Table 1). A chest tube was inserted for drainage. All septic work up that included blood, PF and respiratory cultures were negative. Sonogram of the abdomen showed ascites and liver changes consistent with cirrhosis. The patient condition continued to deteriorate and he died during the hospital admission.

DISCUSSION

The etiology of pleural effusions are diverse and ranges from local (lungs or pleura) to extrapulmonic or systemic diseases.

In many cases the cause is a chronic condition for which the patient is already receiving treatment; therefore, a patient with pleural effusion may present to a pulmonologist or other medical specialist. In up to 20% of cases the cause remains unknown despite extensive investigation.

Chylothorax is a rare finding and is usually an exudative effusion. Fat in the intestines is absorbed into the lymphatics, which drain via the thoracic duct into the systemic circulation. The average flow of chylus in an adult is 2L/day; it increases with food and drink, and decreases significantly with starvation.

ETIOLOGY:

Chylothorax is uncommon and can be divided in non-traumatic (72%) traumatic (28%), and pseudo-chylothoraces.
Non-Traumatic Chylothorax

EVALUATION

In non-traumatic cases, a chest and abdomen CT scan is recommended in order to visualize any tumor or enlarged lymph nodes. A dilated duct can often be seen in cases where lymphatic obstruction produced the leakage. Lymphography can be helpful, as can an MRI.

MANAGEMENT OF NON-TRAUMATIC CHYLOTHORAX

Conservative treatment with diet restrictions is successful in >50% of patients with traumatic chylothorax, but rarely so with chylothorax of other causes. A low-fat diet containing medium-chain triglycerides (which are absorbed into the blood) will decrease chylus production. If diet does not work, the next step is total parenteral nutrition. In non-traumatic cases, spontaneous resolution is less likely.

The success of chemical pleurodesis is limited but could be tried. Surgery is the last resort; ligation of the duct at the level of the diaphragm is successful in up to 90% of patients.

Patients with underlying lymphoma or metastatic cancer frequently respond to therapy directed at the primary tumor or metastatic sites. Some reports showed that 68% of patients with lymphoma and 50% of those with metastatic carcinoma had resolution of the chylothorax after radiation therapy.

CONCLUSION

Pleural effusions are a common finding in any clinical practice. The physicians should be aware of the rare presentations of common diseases. Chylothorax is rare, and should be suspected in patients with the above mentioned pathologies. It will be useful to include the measurement of triglycerides in the routine PF panel. The presence of a chylothorax entitles a poor prognosis especially in patients with liver cirrhosis or KS.
