Quick Review: The Metabolic Cart
T Fujii, B Phillips

Citation

Abstract
This article gives a brief review of the metabolic cart.

TERMS & DEFINITIONS

CALORIMETRY

Direct calorimetry: Measurement of the amount of heat (energy) produced by a subject enclosed within a Chamber.

Indirect calorimetry: Measurement of the amount of heat (energy) produced by a subject by determination of the amount of oxygen consumed and the quantity of carbon dioxide eliminated

- The metabolic cart essentially measures the oxygen consumed and the carbon dioxide produced by the patient and then calculates (using the modified Weir equation) the energy expenditure for the patient
- Weir equation: EE = (3.94 x VO2) + (1.1 x (VCO2))

Indirect calorimetry provides two pieces of information:

1. A measure of energy expenditure as reflected by the resting energy expenditure (REE)
2. A measure of substrate utilization as reflected in the respiratory quotient (RQ)

RESTING ENERGY EXPENDITURE (REE)

REE = 75 % - 95 % of total energy expenditure (diet-induced, environmental, activity)

- Metabolism in brain, liver, heart and kidney is relatively constant (60 - 70 % REE)
- Variability in REE:
  - between people
  - during the day 12 %
  - increases with critical illness
  - day to day - 23 %

Variability in REE can be due to:

- Size
- Gender
- Age
- Work of breathing (2 - 3 %)
- Diet-induced thermogenesis
- Sleep
- Illness
- Starvation
- Fever (13 % per degree C)
- Cold
- Activity
- Drugs

POINTS:

- REE correlates closely with fat free lean body mass.
- Work of breathing normally (2 - 3 %) can be as high as 25% of REE with impending respiratory failure
- Diet-induced thermogenesis normally 8-10% drops
to 4-8% with continues enteral feeds

- REE drops with sleep
- Most disease states increase REE
- 20-50% increase seen with elective surgery and trauma, 100% increase in REE seen with severe burns
- Increases in REE are seen in the flow phase of injury and can be effected by therapy
- Increases in REE can be expected to reflex severity of illness but the response plateaus at
- 2x the REE
- Increases in REE due to acute illness usually return to base line at 7 to 10 days
- Not all critically ill patients become hypermetabolic (35-60%)
- 15-20 % of ICU-patients are found to be normometabolic.
- 10 -20% of ICU-patients are found to be hypometabolic.
- Hypometabolic state may be do to the disease process: specific cancers ,cachexia ,spinal cord injuries paraplegics decreased REE by 10% quadriplegics by 30%
- Long-term starvation reduces EE by 30-40%
- Fever increases REE (13 % per degree C)
- Exposure to Cold /hypothermia increases REE by shivering and nonshivering thermogenesis
- General Activity is responsible for most of the variability in REE.
- Being awake and alert increase EE by 10%.
- Routine nursing care increases EE by 20 -30%.

Medications that affect REE:
- caffeine, aspirin increase EE
- catecholamines and pressor increase EE
- sedatives,analgesics, beta blockers
- general anesthesia decreases EE
- ** Acute hyperventilation increases EE, while Hypoventilation decreases EE

**PREDICTING REE**

Harris-Benedict is correct 80-90% of the time in healthy, normal volunteers. In 10-14% it over-estimates EE. In obese volunteers, the equation predicts EE correctly only 40-64% of the time. In critically-ill patients the Harris-Benedict equation is correct only 50% of the time. For most disease processes Harris -Benedict underestimates EE. Multipliers for various disease states attempt to improve the accuracy of the Harris-Benedict equation (though these multipliers tend to overestimate EE when compared to indirect calorimetry).

- RQ: Derived from actual measurements of VCO2 and VO2
- RQ is the ratio of carbon dioxide produced to oxygen consumed (VCO2 / VO2)
- Reflection of which fuels are being oxidized
- “Non-protein” RQ (npRQ) excludes protein metabolism

**RESPIRATORY QUOTIENT**

Ratio of CO2 produced to O2 consumed.

\[(VCO2 / VO2) = RQ\]

Carbohydrate: \(1gm \text{ C} + 0.83 \text{ L O2} \text{ 0.83 L CO2} + 0.56g \text{ H2O} + 4.17 \text{ Kcal}\)

\(RQ = 1\)

Fat: \(1gm \text{ F} + 2.02 \text{ L O2} \text{ 1.43 L CO2} + 1.07 g \text{ H2O} + 9.3 \text{ Kcal}\)

\(RQ = 0.70\)

Protein: \(1gm \text{ P} + 0.96 \text{ L O2} \text{ 0.78 L CO2} + 0.41 \text{ H2O} + 0.16g \text{ Nu} + 4.3 \text{ Kcal}\)

\(RQ = 0.81\)

Glucose oxidation RQ = 1.0

Fat oxidation RQ = 0.7

Protein oxidation RQ 0.8

Lipogenesis RQ 1.3

(npRQ of 0.85 - 50 % fat and 50 % carbohydrate oxidation)

**“OPTIMAL RQ”**

- Nutrition support should probably provide a balance between carbohydrate and lipid with an RQ in the 0.8 to 0.9 range
Avoidance of RQ's > 1.0 which represents “overfeeding” and potential lipogenesis is a reasonable goal.

**FACTORS THAT AFFECT RQ:**

Those that increase RQ

- Hyperventilation
- Metabolic acidosis leading to increases in carbon dioxide,
- Overfeeding leading to lipogenesis
- Exercise

Those that decrease RQ

- Hypoventilation
- Mild starvation with ketosis
- Diabetes with ketoacidosis or high rates of urinary glucose lose
- Gluconeogenesis
- ETOH metabolism
- Hypothermia via continued gluconeogenesis

Resting energy expenditure of critically ill patients varies widely over the course of the day and over the course of an illness. Measurements from 10 - 23% of an “average” REE can be seen within a 24 hour period. Test patient at rest in quiet, controlled environment. “Steady state” implies a 5 minute interval where the average V02 and the VC02 changes by less then 10% and the average RQ changes by less than 5%.

- Question validity of the test
- Steady state is not achieved
- RQ falls outside of the physiologic range of 0.67-1.3
- Measurements should fall with in the range of V02 (1.7 to 3.4 mL/min/kg) and VC02 (1.4 to 3 mL/min/kg)

**METABOLIC CART SOURCES OF ERROR:**

- FiO2 >60%
- Air leaks (chest tubes etc).
- Hemodialysis (Co2 loss via the dialysis coil)

Use of the metabolic cart can prevent over-feeding, and under-feeding by accurately measuring energy requirements. Overfeeding critically ill patients results in hyperglycemia, hepatic steatosis, R.E.S. dysfunction and increased septic complications. Under-feeding patients can lead to the complications of malnutrition. The use of a metabolic cart can reduce the amount of “unnecessary” TPN which is administered (use of a metabolic cart reduced TPN use from 33,000 liters to 26,000 liters in one study - Mullen et al., Proc Nutr Sos 1991. 50:239-44).
