Dermatophytes and other skin mycoses found in featherless broiler toe webs

T Mbata

Abstract

Featherless broilers which are produced by a complex breeding programme from feathered parents carrying the Sc-gene, dissipates excessive body heat under hot and humid conditions. It has high body weight, and grows very rapidly when compared with standard commercial broiler. Their toe webs are bigger than standard commercial broiler, and could harbor fungi which can cause infections where there is the opportunity. Objectives: To isolate and identify the presence of fungi in toe webs of featherless broiler. Methods: A total of 50 featherless broiler toe web samples were examined microscopically presence of fungi. The samples were examined microscopically and culturally using standard microbiological techniques. Results: The fungi recovered were as follows. Microsporum gypseum 9 (22%), Trichophyton mentagrophytes var. mentagrophytes 5 (12%), Microsporum gallinae 3 (7%), Aspergillus flavus 10 (24%), Fusarium sp 6 (15%), Alternaria alternata 3 (7%) Scopulariopsis brevicaulis 2 (5%) and Candida albicans 3 (7%). Conclusion: The featherless broiler toe webs habors fungi which causes mycotic skin disease and cannot be regarded as ordinary normal flora of toe webs.

INTRODUCTION

Dermatophytes are among the most frequent causes of dermatological problems in domestic animals. They are classified in three genera, Epidermophyton, Microsporum, and Trichophyton which include about 40 accepted species. However, only a few species belonging to the genera Microsporum and Trichophyton are usually the cause of dermatophytes in domestic animal [1]. They are usually divided into three ecological groups according to their main natural host or habitat: the anthropophilic (humans), the zoophilic (animals) and the geophilic (soil).

Animals serve as reservoirs of the zoophilic dermatophytes, and their infections have considerable zoonotic importance. Zoophilic dermatophytes such as M. canis, T. mentagrophytes var. mentagrophytes and T. verrucosum are significant causal agents of human ringworm in many areas of the world [1]. The incidence of dermatophytosis varies according to climate and natural reservoirs. However the pattern of the species of dermatophytes involved in dermatophytosis may be different in similar geographical conditions, both in human and animal [2].

In this study, the occurrence of dermatophytes and other skin mycoses found in toe webs of featherless broilers were investigated.

MATERIALS AND METHODS

COLLECTION OF SAMPLE

A total of 50 fatherless broilers kept at the animal house at 30°c at the Faculty of Agriculture, Hebrew University, Rehovot Campus, Israel were used in the study. Presence of scaling (if any) was noted. Samples of skin scrapings from the interdigital toe webs were taken using a sterile scalpel. Scalpels were changed for each sample to avoid contamination of specimens. The scrapings were collected in a piece of sterile papers, carefully folded, and then placed in an enveloped for storage in air-tight containers to await microscope and cultural analyses.

SAMPLE PROCESSING

MICROSCOPY AND CULTURE OF SAMPLES

A small sample of each scraping was digested by placing it on a microscope slide and adding one to two drops of 20% Potassium hydroxide (KOH). A cover slip was applied and the slide was heated gently over a flame as describd3d by Hainer [3]. Each treated slide was the carefully examined under low (x10) and High (x40) power objectives to observe the fungal forms.

Each scraping was cultured, for dermatophytes onto sabouraud dextrose chloramphenicol actidione agar. A
duplicate inoculation of the sample was also cultured on sabouraud’s dextrose cycloheximide agar. For non dermatophytes, cultures were made on sabouraud dextrose agar supplemented with chloramphenicol to eliminate bacteria. All cultures were incubated at 28°C for up to 4 weeks. Fungal isolates were then subcultured onto plates of sabouraud’s agar and potato glucose agar. The isolates were examined macroscopically and microscopically following staining with lactophenol cotton blue wet mount technique. The dermatophytes species were identified by gross and microscopic morphology and by in vitro tests, if required based on the criteria enumerated by Rebell and Taplin [4] and Frey et al [5]. The yeast’s were identified with the taxonomic criteria outlined by Lodder [6]. Each isolate was tested for the ability to ferment and/or assimilate different carbon sources. They were also tested for their ability to produce Urease, utilize KNO₃ as the sole nitrogen source and grow at 37°C.

RESULTS
A total of 50 featherless broilers who presented with suspected superficial mycoses in the toe webs were examined during the investigation. Forty-one broilers (82%) were found to be mycologically positive by microscopy and culture. Only 5 chickens showed some scaling in their toe webs. The organisms recovered from those who presented with scaling were Microsporum gallinae, Microsporum gypseum, Trichophyton mentagrophytes var. mentagrophytes and Candida albicans. Many fungi belonging to 7 different genera were recovered from the toe webs of 41 of the 50 featherless broilers samples studied. They included M. gypseum 9 (22%), M. gallinae 3(7%), T. mentagrophytes var. mentagrophytes 5 (12%), Fusarium sp 6 (15%), Scopulariopsis brevicaulis 2 (5%), Alternaria alternata 3 (7%), Aspergillus flavus 10 (24%) and Candida albicans 3 (7%). Non dermatophytes were recovered from 21 (51%) of the positive cases, dematophytes from 17 (42%) and yeast from 3 (7%). The frequency of distribution of individual isolates is shown in Table 1. Microsporum gypseum and Aspergillus flavus were the most commonly encountered dermatophytes and non dermatophytes respectively; while Candida albicans was the only yeast recovered.

DISCUSSION
The study showed that toe webs of featherless broiler that may be considered healthy harbor varieties of dermatophytes non-dermatophytes and yeast. According to Lison et al., [7] pathogenic yeast can be isolated from healthy-looking toe webs. Featherless broilers according to Aaron [8] do not suffer from heat related mortality and can survive in low and hot environmental temperature.

In this study, some of the fungi isolated were also recovered by Oyeka [9] on human toe webs. This could be because keepers of most domestic animals (Poultry) entered their environment (habitat) with bare-foot (to avoid cross-infection), but infected human foot web may cross-infect the birds. Infection of human foot could occur as a result of wearing of shoes [8] as this may provide warmth and moisture on the toe webs required by fungi to grow and cause damages in the tissue.

The occurrence of dermatophytes has been previously reported in domestic animals [1]. The study recovered dermatophytes and other skin myxoses from the toe webs of featherless broilers. They included Microsporum gallinae, Microsporum gypseum, Trichophyton mentagrophytes var. mentagrophytes, Alternaria alternata, Aspergillus flavus,
Fusarium sp, Scopulariopsis bervicaulis and Candida albicans

Microsporum gypseum was the most commonly isolated dermatophytes. Others, Microsporum gallinae and Trichophyton mentagrophytes var. mentagrophytes are regular pathogens of foot infection [9, 10]. These fungi have been found in soil/dust in many parts of the world (11) and their presence in this study could be attributed to poor sanitation of the broilers environment.

The presence of Aspergillus flavus, Fusarium sp., Alternaria alternata and Scopulariopsis brevicaulis which are common soil saprophytes may be due to their ubiquitous nature of their spores in the environment and which can always be carried on healthy skin, toe webs inclusive. Fusarium sp has also been recovered from cases of foot infection, either alone or mixed with other pathogens [12]. This finding agrees with our study which shows that most fungi recovered were either alone or mixed with other Pathogens. Scopulariopsis brevicaulis has also been isolated in an indoor environment and can often cause inflammatory lesion on the skin [13, 14].

Candida albicans an opportunistic patogens known to produce a diverse range of mucosal and cutaneous as well as subcutaneous and systematic mycoses [15] was also isolated.

In conclusion, featherless broilers toe webs although bigger than that of feathered broiler harbor less fungi. This may be attributed to the particular temperature where they are kept with little contact with dust and soil. These birds can survive in low and hot environmental conditions in order to fully express their genetic potential of rapid growth and high meat yield unlike the feathered broilers. Finally the fungi recovered from the toe webs have been implicated in cases of mycotic skin disease and therefore cannot be regarded as ordinary normal flora of toe webs. These pathogens can cause infections under favourable conditions.
