Abstract

AIMS:
To evaluate the role of Magnetic Resonance Imaging in diagnosing osteoarthritis of knee joint and to correlate MR imaging findings of osteoarthritis with that of radio graphically diagnosed osteoarthritis in Indian population.

METHODS AND MATERIAL: One hundred twenty eight patients formed the study group in a prospective fashion. All patients underwent Antero posterior radiography of affected knee in weight bearing extended positions, KL score was determined and subsequently MRI of the knee was performed. Then Magnetic Resonance Imaging (MRI) findings were correlated by radiographic findings.

STATISTICAL ANALYSIS USED: Data were analyzed using statistical software package, STATA 9.2 and the association was considered to be significant if "P" value was <0.05.

RESULTS:
The tibiofemoral compartment was more frequently and more severely involved in osteoarthritis of knee joint than the patellofemoral compartment and medial tibiofemoral joint was most commonly involved. Majority of MRI findings in tibiofemoral compartment of knee joint and KL score are well correlated.

INTRODUCTION

Worldwide, osteoarthritis is the most common form of arthritis. Osteoarthritis (OA) is a highly prevalent disease, and the prevalence is expected to increase substantially as a greater proportion of the population exceeds 60 years of age[1,2]. The diagnosis of osteoarthritis is based primarily on the history and physical examination, but radiographic findings, including asymmetric joint space narrowing, subchondral sclerosis, osteophyte formation, subluxation and distribution patterns of osteoarthritic changes, can be helpful when the diagnosis is in question. Historically, the primary modality for imaging evaluation of OA has been radiography, although the limitations of radiographic parameters for OA evaluation are well-documented. Because radiographs are a two-dimensional composite of complex three-dimensional structures, the sensitivity for observation of features such as osteophytes, bone eburnation, and other subchondral bone abnormalities on them is limited. Lastly, radiographically observed abnormalities in OA often correlate imperfectly with clinical symptoms[3-6]. This finding reinforces the evolving concept that OA of the knee is a whole-organ disease and that MR imaging is capable of showing the bone and soft-tissue evidence of OA of the knee[7].

Recent focus on the development of disease-modifying therapeutic agents for OA has emphasized the need for imaging techniques capable of depicting relevant early abnormalities of OA over relatively short times. Simultaneously, there is increasing acknowledgment that OA, particularly in the knee, can be regarded as a whole-organ degenerative process[7], with an emphasis on the contribution of multiple articular and periarticular abnormalities in the clinical expression of the disease. Dr. Peterfy, co-founder and Chief Medical Officer of Synarc, was the first to develop whole-organ MRI scoring (WORMS) for the knee. WORMS combines semi-

quantitative assessments of a total of 11 structural features, including the articular cartilage, subarticular marrow-edema, cysts and bone attrition in 8 different locations in the knee; osteophytes along 16 articular margins; the medial and lateral menisci; the anterior and posterior cruciate ligaments; and the medial and lateral collateral ligaments [8]. MRI is an excellent diagnostic modality in osteoarthritis. The superior soft tissue contrast of MRI provides the ability to diagnose cortical bone, articular cartilage and soft tissues abnormalities in the joints that improves early detection of osteoarthritic changes in knee joint.

The study was performed to grade various stages of osteoarthritis by using Kellgren-Lawrence grading scale , to evaluate the osteoarthritis of knee using magnetic resonance imaging , to correlate MR findings of osteoarthritis with that of radiographically diagnosed osteoarthritis.

SUBJECTS AND METHODS
One hundred twenty eight patients have formed the study group in a prospective fashion. All patients underwent Anteroposterior radiography of affected knee in weight bearing extended positions and subsequently MRI of the knee was performed. For the reporting of abnormalities at MR imaging according to compartment, simple counts (numbers and percentages) were estimated. In the analysis of MR imaging findings for the OA of the knee, the single knee (the most symptomatic knee at inclusion in the study) for each subject was analyzed. For subjects in whom both knees equally fit the categorical criteria, the self-described dominant knee was chosen as the examined knee. Patients with knee pain/stiffness/limitation of movement were included and osteoarthritis of knee was diagnosed by clinicoanatomical American Rheumatism Association Criteria, viz;

1. Osteophytosis
2. Knee pain
3. Age >40 yrs
4. Joint stiffness<30 minute
5. Crepitus

For diagnosing osteoarthritis presence of 1,2 and one of 3,4 or 5 is essential.

Exclusion criteria were claustrophobia, non cooperative patients, patients with obvious inflammation, secondary osteoarthritis e.g. trauma, operated knee joint, inflammatory arthritis e.g. rheumatoid arthritis, morning stiffness>1 hr in hand joints, diseased ipsilateral hip joint, fibromyalgia, depression, local wound/ulcer around knee joint or presence of peripheral neuropathy.

RADIOGRAPHIC FINDINGS AND KL SCORE
Radiographic grading of severity of osteoarthritis

Radiographic Assessment was done by Anteroposterior radiographs of the knee, obtained in a weight-bearing extended position by using a standard radiographic technique. Scores to all radiographs were assigned by using the Kellgren-Lawrence scoring system [9].

TECHNIQUE OF MAGNETIC RESONANCE IMAGING IN KNEE OSTEOARTHRITIS

MR imaging of the knee was performed with a 1.5-T MR imager (Sigma; GE Medical Systems), by using a quadrature receiver knee coil for signal reception. Since patients with symptomatic knees were examined by using a fairly long acquisition protocol, patients were immobilized by using hook-and-loop straps. MR Imaging were performed by using T2 FSE sequence in axial plane; PD Fat Sup, T1 SE, T2 fr FSE and SPGR sequence in sagittal plane and STIR FSE,T2 GRE & T1 FSE in coronal plane. For STIR and SPGR matrix of 256 x192 was used. For rest of the sequences matrix of 320x224 was used. FOV (field of view) of 18 mm was used in all sequences. Slices were obtained at 4-5 mm thickness with an interscan gap of 0.5-1 m. In SPGR sequence slice thickness was 2mm, with no spacing. Each knee was assessed globally and according to compartment for 12 MR imaging–defined parameters. The compartments in knee joint were medial and lateral articulating surface of femur(MF and LF respectively), medial and lateral articulating surface of tibia(MT and LT respectively), medial and lateral articulating facets of patella (PMF AND PLF respectively) and trochlea of femur (FT).
Defects of cartilage.—Location, severity, and approximate size of defects of cartilage in three compartments (medial femorotibial, lateral femorotibial, patellofemoral compartments) and seven specific surfaces (medial articular surface of tibia, medial articular surface of femur, lateral articular surface of tibia, and lateral articular surface of femur, trochlea and medial and lateral patellar facets) were assessed. Severity scoring was based on the Noyes arthroscopic system, which was modified for MR imaging [10]. Cartilage was assigned grades as follows: grade 0, normal; grade I, internal signal intensity alteration only; grade IIA, defect of cartilage of less than 50%; grade IIB, defect of cartilage of 50%–99%; grade IIIA, 100% defect of cartilage with no bone ulceration; or grade IIIB, 100% defect of cartilage with subjacent bone ulceration.

Subchondral trabecular BME.—BME was defined as noncircumscribed areas of abnormally high signal intensity on IW fast spin-echo images obtained with fat saturation in a subchondral location and verified in at least two imaging planes [11,12]. BME lesions were recorded according to site and severity in the following manner: grade 0, normal; grade 1, largest diameter of less than 10 mm; or grade 2, largest diameter of greater than 10 mm.

Marginal osteophytes.—Osteophytes were defined as any abnormal bone growth that arose from the margin of the involved compartment. Tibial spine growths were considered as osteophytes in their respective compartments only if there were definite ex crescences, as opposed to mere “pointedness” of the tibial spines. Osteophytes in each compartment were assigned grades as follows: grade 0, no osteophytes; grade 1, osteophytes of less than 5 mm; or grade 2, osteophytes of greater than 5 mm [13].
Evaluation Of Osteoarthritis Of The Knee With Magnetic Resonance Imaging And Correlating It With Radiological Findings In The Indian Population.

Figure 3
Figure 3 GRADE II OSTEOPHYTE IN MEDIAL FEMORAL CONDYLE AND GRADE 1 OSTEOPHYTE IN LATERAL FEMORAL AND MEDIAL TIBIAL.

Subchondral cysts.—Subchondral cysts were defined as marginated circular or oval areas of hyperintensity (similar to that of fluid) on IW fast spin-echo images obtained with fat saturation in a subchondral location [14]. Cysts were assigned grades according to compartment as follows: grade 0, normal; grade 1, less than 10 mm in diameter; or grade 2, greater than 10 mm in diameter.

Subchondral sclerosis.—Definite focal thickening of the subchondral bone, consisting of low signal intensity on both IW spin-echo images and IW fast spin-echo images obtained with fat saturation, was classified as sclerosis [15]. Sclerosis was assigned grades according to each compartment as follows: grade 0, normal; grade 1, sclerosis with depth extending less than 5 mm; or grade 2, sclerosis with depth extending more than 5 mm.

Joint effusion.—Joint effusion was defined as the presence of greater than expected physiologic amounts of synovial fluid in the lateral or medial patellar recesses that exceeded 10 mm in width [16]. Joint effusion was assigned grades as follows: grade 0, normal; grade 1, small effusion; or grade 2, moderate or large effusion.

Baker’s cyst/Synovial cysts.—Synovial cysts were fluid-filled collections that arose from the joint, extended between the semimembranosis and semitendinosis tendons and the medial head of the gastrocnemius muscle, or were in a less typical site, if confirmed to be in continuity with the joint [16]. Meniscal cysts, ganglionic cysts, and other nonspecific periarticular cysts were not included in the analysis. Synovial cysts were assigned grades according to a semiquantitative scale as follows: grade 0, normal; grade 1, small; or grade 2, large.

Figure 4
FIGURE 3 JOINT EFFUSION AND BAKER’S CYST

Synovitis.—Synovitis was defined as increased linear striations within the infrapatellar (Hoffa) fat pad and irregular thickening at the margin of the fat pad with the articular cartilage [17,18]. These abnormalities consisted of low signal intensity on IW spin-echo images and intermediate to high signal intensity on IW fast spin-echo images obtained with fat saturation. Synovitis was assigned grades thus: grade 0, normal; grade 1, mild; or grade 2, moderate to marked.

Meniscal abnormalities.—By using accepted MR imaging criteria described in a study of Crues et al [19], intrameniscal abnormalities and frank tears were assigned grades that were recorded as follows: grade 0, normal or globular intrasubstance abnormalities (grade 1 of Crues et al); grade 1, linear intrasubstance meniscal abnormality (grade 2 of Crues et al); grade 2, nondisplaced tear (grade 3 of Crues et al).
Ligamentous abnormalities.—Cruciate ligamentous abnormalities were assigned grades as follows: grade 0, normal; grade 1, increased edema within or surrounding the ligament, with a normal course, and at least some intact fibres present; or grade 2, complete tear, acute or chronic. Collateral ligamentous abnormalities were assigned grades as follows: grade 0, normal ligament; grade 1, substantial peri ligamentous edema, with the ligament intact; grade 2, partial tear; or grade 3, complete tear.

Osteochondral bodies/loose bodies—Loose bodies can be classified into several categories: Osteocartilaginous, hyaline cartilaginous, fibrous cartilaginous, and other. Osteocartilaginous loose bodies are composed of bone and cartilage and are thus detectable radiographically because of the osseous component. Hyaline cartilaginous loose bodies are radiolucent and are usually caused by trauma, originating from the articular surfaces of the patella or the femoral or tibial condyles. Fibrous cartilaginous loose bodies are also radiolucent, occur less frequently, and result from meniscal fragment.

Subluxation in knee joint.

STATISTICAL METHODS

Sample profile was described in terms of means ± SD and proportion. Chi square (c2) statistics was applied to test the association between two categorical variables. Spearman’s correlation was reported to estimate the strength of association between KL score and severity of osteoarthritis. Two sample t-test was applied to test the difference between the mean of two different groups, if data was normally distributed otherwise Mann Whitney test was applied. In case of more than 2 groups, one way Analysis of Variance or Kruskal Walli’s test, whichever is applicable, was used. Data were analyzed using statistical software package, STATA 9.2 and the difference was considered to be significant if ‘P’ value was <0.05.

RESULTS

All the patients presented at an age equal to or more than 40 years. Most of the patients (n=48, 37.50%) were 40-45 years of age. The study population included ninety two females (71.87%) and thirty six males (28.13%) and a higher incidence of osteoarthritis was seen in female population in the age group of 40-45 years Also the peak prevalence of osteoarthritis in our study was at a lower age in females as compared to males.

Our study population was graded by Kellgren-Lawrence scores according to the severity of osteoarthritis as diagnosed on X-ray features. 48 patients (37.50%) of study population were categorized as having a KL score of Grade 2, 60 patients (46.87%) were diagnosed as having a KL score of Grade 3 and 20 patients (15.63%) were diagnosed as having a KL score of Grade 4. The association between various compartment specific MRI findings and KL score have been shown in table.

Figure 5

TABLE 2 INCIDENCE OF VARIOUS COMPARTMENT SPECIFIC MRI FINDINGS AND COMPARISON WITH KL SCORE (STATISTICALLY SIGNIFICANT ASSOCIATION HAS BEEN MARKED BY ASTERIX*)

There is a high correlation between MR severity of osteophytes, subchondral cysts, bone marrow edema, cartilage defects and radiographic findings (P value = 0.000, 0.000, 0.000, 0.000, 0.030, 0.001, 0.000; P=0.40, 0.000, 0.000
A significant association with high KL score was found with meniscal and ligamentous injuries (P = 0.000 and 0.001 in medial and lateral meniscal injuries, P = 0.000 and 0.004 in medial and lateral collateral ligament injuries and P = 0.032 and 0.001 in anterior and posterior cruciate ligamentous injuries respectively). A significant statistical association was seen between radiographic findings and Baker’s cysts, joint effusion, and synovitis (P = 0.000, 0.000, 0.001 and 0.000 respectively). Osteochondral bodies were seen in 15.63% of study population and were significantly associated with KL score (P = 0.000).

**DISCUSSION**

MRI, being a multiplanar diagnostic tool, is an excellent modality for the evaluation of patients of osteoarthritis of the knee joint. It accurately defines the extent of bony and soft tissue changes in the knee joint. In this study MRI was compared with a plain radiograph of knee joint and MRI was found to be a much better diagnostic tool for evaluating the changes in bones and soft tissues in osteoarthritis of the knee. Few findings from our study are noteworthy. Firstly, frequency and severity of MRI changes in various tissues strongly correlated with Kellgren Lawrence grade of osteoarthritis of the knee at radiography. Secondly, MR imaging defined abnormalities were more frequent in the tibiofemoral compartment than in the patellofemoral compartment.

In our study the tibiofemoral compartment which was more frequently and more severely involved in osteoarthritis of the knee joint than the patellofemoral compartment. In western population, it was the patellofemoral compartment which was more frequently and more severely involved. This difference is due to sitting in squatting posture in Indian population. Prolonged squatting has been associated with development of osteoarthritis of the knee joint in the tibiofemoral compartment but only slightly associated with development of osteoarthritis in the patellofemoral compartment.

Most frequent site of osteophytosis was the medial tibiofemoral joint in our study (100%) while in Curtis W. Hayes et al. study the patellofemoral compartment was the most frequent site of osteophytes. The incidence of Grade II osteophytes was highest in the medial condyle of the tibia (46.87%) of the study population. The next most common site where Grade II osteophytes were seen was the medial condyle of the femur.

The most common site of bone marrow edema in our study was the tibiofemoral compartment with the highest incidence in the medial condyle of the femur (78.12%) while in a previous study the patellofemoral compartment was the most common site showing bone marrow edema. This difference could also be explained by the squatting posture adopted by the Indian population.

Subchondral cysts were also most commonly found in the tibiofemoral compartment i.e. in the medial condyle of the femur (62.50%) followed by in the medial condyle of the tibia (53.12%). Grade II subchondral cysts were most frequently seen in the medial condyle of the tibia (25%).

Almost all patients in our study showed presence of cartilage...
in our subjects, that is why radiographically determined used in the categorization of the radiographic severity of OA explained, as lateral or skyline views of the knee were not correlation between MRI and KL score for diagnosing compartment of knee joint and KL score. There is a poor majority of MRI changes of osteoarthritis in tibiofemoral We found a statistically significant correlation between presence of subluxation of tibia, lateral subluxation being the most common location for grade IIIB lesions in their study. It is noticeable that defects of cartilage of Grade II a or higher and bone marrow edema were evident on MR images, even on those knees which were classified as normal on radiography In our study subchondral sclerosis and cysts were more commonly seen in tibiofemoral joint than the patellofemoral joint as reported earlier in literature. Medial articulating surface of tibia showed the highest frequency of subchondral sclerosis (75% of study subjects) and also subchondral sclerosis of larger size, followed by medial articulating surface of femur (59.37% of study subjects). Majority of subchondral cysts and subchondral sclerosis were reported by Curtis W. Hayes et al seen in patellofemoral compartment. The incidence of medial and lateral meniscal injuries are almost equal in our study (90.62% and 96.87% respectively) of which 46.87% and 53.13% of patients showed Grade II tears of medial and lateral meniscus respectively. These findings are in accordance with the previous study. Collateral ligament injury was rarely seen in our study. Anterior cruciate ligament and posterior cruciate ligament injury was seen in 25% and 34.37% of cases, respectively. Joint effusion of varying grades was seen in 78.13% of cases in our study. Mild grade of synovitis was seen in 25% of patients. Baker’s cysts of varying grades were seen in 40.63% of study population. Osteochondral bodies were seen in 15.63% patients. 25% patients showed presence of subluxation of tibia, lateral subluxation being the most common. We found a statistically significant correlation between majority of MRI changes of osteoarthritis in tibiofemoral compartment of knee joint and KL score. There is a poor correlation between MRI and KL score for diagnosing changes in the patellofemoral compartment. This could be explained, as lateral or skyline views of the knee were not used in the categorization of the radiographic severity of OA in our subjects, that is why radiographically determined patellofemoral involvement was relatively underdiagnosed. The disparity in sensitivity between MR imaging and standard radiography for detection of abnormalities, especially in the patellofemoral compartment, may partly explain the observation that anatomical changes in OA of the knee long precedes the radiographic evidence of OA of the knee but can be diagnosed by MRI at an early stage. Our data show that there were more frequent and more severe abnormalities detected at MR imaging as the radiographically determined grades of OA of the knee increased. Increasing Kellgren Lawrence scores were associated with more frequent and more severe defects of cartilage, bone marrow edema, osteophytes, subchondral sclerosis and subchondral cysts in tibiofemoral compartment, joint effusion, osteochondral bodies and presence of meniscal tears. These finding reinforce the evolving concept that OA of the knee is a whole-organ disease and that MR imaging is capable of showing the bone and soft-tissue evidence of OA of the knee at an early stage.
